S. Kaniszewski and J. Rumpel Research Institute of Vegetable Crops, Skierniewice. Poland

Abstract

The effect of soil type and irrigation on the yield of celeriac was investigated in the years 1976-1978 in a microplot experiment. The microplots located outdoors were built as bottomless, concrete containers of 5 m² each. Prior to the experiment the microplots were filled up with seven following soil types: black soil, chernozem, brown soil, alluvial soil, pseudo-podzols No. I and No. II and with peat soil.

Each of the microplots was divided into two parts, of which one was irrigated according to tensiometer indications when the soil moisture dropped to 70 percent of the field capacity, whereas the other - was

subject to natural precipitation only.

The water rate per single irrigation was calculated for each soil type with the mim to restore the soil moisture to the field capacity when-

ever water deficiency occurred.

Independently of the irrigation, highest yields of celeriac cv. Odrzanski were obtained on chernozem, alluvial and peat soil with 3 year averages of 4.44, 4.39 and 4.31 kg per m2 respectively. The brown, black and podzolic soil No. I produced intermediate yields of 3.36, 3.30 and 3.01 kg per m² respectively whereas lowest yields of 2.16 kg per m² were produced on podzolic soil No. II. Irrigation increased significantly the yield of celeriac. The average yield from all irrigated soils was 4.0 kg as compared to 3.1 kg per m2 of the non-irrigated ones. The effect of irrigation was related to the soil type.

The brown and pseudo-podzol soil No. I gave highest yield increase of 59 and 45 percent respectively whereas these of the peat soil averaged

The amount of water required for irrigation during the vegetation 10 percent only. period varied with the soil and lowest on peat soil with 267 and 73 millimeters respectively.

Introduction

Wide research works have shown that the effect of irrigation is closely related to soil properties. The most important factor determinating the need of irrigation is the available water capacity of the soil and water requirements for irrigation of a certain soil are related to the soil texture, organic matter content and soil structure. These soil properties affect not only the water holding capacity of the soil but also the water lesses due to evaporation.

The problems of the response of different soil types to irrigation and the required water doses for different soils and crops is very important for the grower. Earlier work on this topic (Kotryf, 1973 and Sypien et al., 1979) showed that carrots and onions responded differently to irrigation and different soil types. Also the required water doses

The objective of this work was to study the effect of soil type and were different. irrigation, including water doses, on the yield of celeriac.

Material and methods

The experiments were conducted in the years 1976-1978 in microplots located on the experimental field of the Research Institute of Vegetable Crops at Skierniewice. The microplots of 5 m2 each were made as bottomless, concrete containers, with walls reaching 20 cm above and 100 cm below the ground level.

The bottom part of the microplots was permeable, due to filling with a

20 cm layer of coarse sand and a drainage pipeline underneath.

Following 7 soil types were involved in the experiments: black soil, alluvial soil, pseudo-podzolic soil I and II, loessial chernozem, brown soil and low moor peat soil. The soils were transferred into the microplots in layers with an attempt to reproduce a natural soil deposit. Some properties of the soils used are given in table 1.

Each of the micro-plots was divided into two parts of which one was irrigated according to tensiometer readings when the soil moisture

dropped to 70 percent of the field capacity.

The tensiometers were installed at the depth of 30 cm.

Irrigation rates were calculated for each soil type with the aim to

bring up the water content to the field capacity (table 2).

Nitrogen fertilization in the total amount of 200 kg n/ha was performed in three dosese of which 1/3 was applied broadcast prior to planting and 2/3 in two sidedressings. The phosphorus and potassium fertilization was based on soil analyses and the doses were calculated to attain the soil fertility level of 80 mg phosphorus and 200 mg potassium per liter of soil.

Celeriac, variety Odrzanski (Oderdorfer), from transplants produced

in hotbeds was planted at a distance of 40 x 30 cm.

Results and discussion

The influence of the soil type and irrigation is shown in table 3. The yields of celeriac were differentiated in the years of experiment, which was due to varied climatic conditions. However, in all years of experiment the yields showed similar tendencies. Regardless of the irrigation, highest yields of celeriac were obtained on the chernozem, alluvial and peat soil, where the 3-year averages amounted 4.44, 4.39 and 4.31 kg per m2 respectively. The brown soil, black soil and pseudo-podzolic soil I gave intermediate yields of 3.36, 3.30 and 3.01 kg per m2 respectively, which were significantly lower as these obtained from the first group of soils. The lowest yields averaging 2.16 kg per m2 were produced on pseudo-podzolic II.

The irrigation increased significantly the yield of celeriac, however, the effect was related to the climatic conditions in single years of the experiment. The average yield increase reached 11.4 percent for the years 1977 and 1978 and 60.1 percent for the year 1976. Independently of the scil type the irrigated plots produced in a 3-year period an average yield of 4.0 kg per m whereas the yield from the not irrigated ones averaged only 3.13 kg per m2, thus irrigation resulted in an increase

of 27.8 percent.

The effect of irrigation was related to the soil type. The highest yield response was observed on the brown soil(59 percent) and the pseudopodzelic soil I (45 percent), whereas the peat soil with only 10 percent yield increase showed the lowest response. The yield increase due to irrigation was not only related to the water capacity of the soils. On soil with smaller water capacity e.g. chernozem and alluvial soil the latter responded with a higher yield increase.

Similar higher was the response of the brown soil in spite of its higher water capacity as compared to that of pseudo-podzolic and black soil. This allows to draw a conclusion that by determining the need for irrigation one should not only consider the water capacity of different type of soils but also other soil properties, presumable their structure, construction and soil profile and so on.

Also the seasonal water consumption was related to the soil type (figure 1). The highest quantity of water for irrigation was used on the brown soil (267 mm) and the lowest on the peat soil (73 mm).
